138 pages

Master of Arts

The University of Texas at Austin

Like other analytical techniques, flameless atomic absorption is subject to matrix or interference effects. Upon heating, nitrate and sulfate salts decompose to generate oxidizing species such as nitrogen dioxide or sulfur trioxide. These concomitant oxidants are capable of gas phase reactions with the analyte atoms, thereby reducing the analyte free atom concentration and thus decreasing the analyte absorbance signal. The effects of sodium nitrate, potassium nitrate, sodium sulfate or potassium sulfate on the absorbance signal of iron, nickel, tin, chromium, silver, and copper was studied utilizing both the graphite filament atomizer and the graphite furnace atomizer.

Thermodynamic calculations were employed to explain/predict the effects of oxygen on the analyte free atom concentration. An optical system was developed which allows the simultaneous measurement of the transient absorbance signal at various spatial zones with the commercial furnace atomizer.

AFIT RESEARCH ASSESSMENT

70-151

The purpose of this questionnaire is to ascertain the value and/or contribution of research accomplished by students or faculty of the Air Force Institute of Technology (AFIT). It would be greatly appreciated if you would complete the following questionnaire and return it to:

AFIT/NR
Wright-Patterson AFB OH 45433

Research Title: Flameless Atomic Absorption Spectroscopy:
Effects of Nitrates and Sulfates

Author: Capt Nils Akerlind, Jr.

Research Assessment Questions:

1. Did this research contribute to a current Air Force project?

a. Yes b. No

2. Do you believe this research topic is significant enough that it would have been researched (or contracted) by your organization or another agency if AFIT had not?

a. Yes b. No

3. The benefits of AFIT research can often be expressed by the equivalent value that your agency achieved/received by virtue of AFIT performing the research. Can you estimate what this research would have cost if it had been accomplished under contract or if it had been done in-house in terms of manpower and/or dollars?

a. Man-years _____. b. \$ _____

4. Often it is not possible to attach equivalent dollar values to research, although the results of the research may, in fact, be important. Whether or not you were able to establish an equivalent value for this research (3 above), what is your estimate of its significance?

2. Highly Significant b. Significant c. Slightly Significant d. Of No Significance

5. AFIT welcomes any further comments you may have on the above questions, or any additional details concerning the current application, future potential, or other value of this research. Please use the back of this questionnaire for your statement(s).

CHAPTER I. INTRODUCTION

Since its introduction by Walsh in 1955,¹ atomic absorption spectroscopy has evolved into the analytical method of choice for trace and ultratrace elemental analysis. This technique enjoys widespread applicability (60-70 elements) coupled with limited sample preparation, but is hindered by its nonadaptability to simultaneous multielemental analysis.

Flameless atomic absorption spectroscopy, pioneered by L'vov,² employs an electrothermally heated atomizer instead of a flame to produce the free atoms required for analysis. Because of efficiency of sample introduction and atomization, together with lower background noise, it is more sensitive than flame atomic absorption by a factor of 20-500.³ Flameless atomic absorption permits the direct analysis of both solid and liquid samples and is ideally suited to microsample analysis. It is possible to detect 10^{-12} - 10^{-14} g. of the analyte and consequently is often the method of choice for ultratrace analysis.

There are two basic types of atomizer designs; the filament, and the furnace. The

filament atomizer is an open system in which the analyte is atomized into the space above the atomizer. The West-type filament atomizer⁴ consists of a rod clamped between two water-cooled support electrodes. The filament is usually made of graphite, but may be a Ta ribbon⁵ or graphite coated with various refractory materials such as Ta, W⁶ or pyrolytic graphite.⁷ In almost all atomizer designs an inert sheath gas, usually Ar or N₂, is used to minimize the entrainment of air and subsequent oxidation of the atomizer.

In the furnace atomizer the analyte sample is contained within the volume of the furnace. This allows for increased heating of the gas phase and for interactions with the furnace walls. Generally the transient analyte absorbance signal persists longer in the furnace atomizer than the filament atomizer and observed interferences are minimized. There are several furnace designs. The L'vov furnace⁸ has evolved into a hollow graphite tube approximately 40 mm in length with an inner diameter from 3 to 5 mm. This furnace is preheated up to 2500°C and the sample is then introduced and atomized by means of a secondary electrode plug in the bottom of the furnace. The light from the source,

typically a hollow cathode lamp, an electrodeless discharge lamp, or a continuum source, passes longitudinally through the furnace.

The Massmann furnace⁹ is composed of a long (approximately 50 mm) graphite cylinder mounted between two electrodes. The sample, in liquid form, is introduced onto the furnace wall through a small hole in the top of the furnace. A modified Mini-Massmann furnace (9 mm long, 3 mm inside diameter) has been adapted by Varian Techtron for commercial manufacture. Atomization of the sample from the furnace wall occurs as the entire furnace is rapidly heated to a preselected final temperature. This is in contrast to the L'vov furnace where the sample is atomized into a nearly isothermal environment. There are many other atomizer designs including Ta boats,¹⁰ wire loops,¹¹ graphite crucibles,¹² graphite braids,¹³ etc., which were developed for specific studies but are not in widespread use.

Once the liquid sample has been introduced, the subsequent heating cycle generally is composed of three stages; the dry, the ash, and the atomize. During the dry step, the solvent is gently evaporated by increasing the temperature of the atomizer to near

the boiling point of the solvent. The ash stage allows for the pyrolysis of the sample matrix by increasing the atomizer temperature to a value intermediate between the drying temperature and the appearance temperature of the analyte. The ash is routinely employed for samples with organic matrices. The atomization step produces the free analyte atoms by quickly raising the atomizer temperature to a preset final temperature (1500-3000°C) and maintaining that temperature until the transient analyte signal has disappeared. Hydrogen gas is sometimes mixed with the inert sheath gas to create an enhanced reducing environment for the analyte and thereby minimize some matrix problems.¹⁴

The theoretical and mathematical approaches to free atom formation and the transient analyte signal have been attempted and are documented in the literature.¹⁵⁻²² Johnson and West²¹ developed a simplified model to explain atomization from a graphite filament atomizer. This model has been expanded and enhanced by the work of Torsi and Tessari.^{17, 19, 20} Their mathematical model agrees well with empirical observations of the absorbance signal of Ni and Pb vaporized from a filament atomizer under carefully controlled conditions.

L'vov has studied the atomization process in the furnace atomizer and has developed a simplified model for the general shape of the absorbance signal. In this model the vaporization rate of analyte is assumed constant and the analyte loss from the observation zone is governed solely by diffusion. Two fundamental parameters developed by L'vov have become widely used in the characterization of the absorbance signal. Tau one (T_1) is the time required for the absorbance signal to rise from the appearance time to the maximum peak height, while tau two (T_2) is the time required for the absorbance signal to fall from the maximum peak height to a value of $1/e$ of the maximum. Faulk²² has treated appearance and diffusive loss of the analyte for both the filament and furnace atomizer. Empirical studies aimed at elucidating the mechanistic pathway to the formation of free atoms in the furnace atomizer have been addressed by Sturgeon and Chakrabarti.¹⁶ Utilizing early time absorbance data, they calculate approximate activation energies for various processes which lead to free analyte atom formation. They conclude that the appearance of the free metal is preceded by such species as the metal dimer, metal oxide, or

metal chloride.

As with most analytical techniques, flameless atomic absorption spectroscopy is subject to matrix or interference effects. Due to longer residence times within the analytical volume, higher local concentrations of analyte and interferent, and somewhat lower temperatures, many interferences are more pronounced when flameless atomization is employed in place of flames. While the exact cause of many matrix effects is not fully understood, some interferences are thought to arise from alterations in the graphite surface by the matrix. Similarly, a matrix with a high salt content may change the contact between the graphite and the analyte thereby altering the analyte release mechanism. Some analytes form refractory carbides²³ and are particularly difficult to vaporize. Prevolatilization and loss of the analyte as a molecular species is known to occur and is best documented for halides.^{24,25} Gas phase reactions which deplete the analyte free atom concentration, thereby reducing the analyte absorbance signal, have been studied in this laboratory.^{26,27}

The original goal of this thesis research was to determine the effect of nitrates and sulfates

on the analyte signal in the commercial graphite furnace atomizer and to relate this data to the graphite filament. During the course of this research, the reactions of the thermal decomposition products of the added nitrate and sulfate anions with the analyte above a graphite filament atomizer were reexamined, and an optical system for gathering simultaneous time and spatial absorbance data within the graphite furnace atomizer was developed. The latter development was used to provide additional insight into reactions occurring within the tube-type atomizer that is not normally available using the spatially integrating optics of the commercial instrument.

CHAPTER II. GAS PHASE INTERFERENT REACTIONS

2.1 Effects of Nitrate and Sulfate Concomitants

Most samples and standards for analysis by flameless atomic absorption spectroscopy are routinely dissolved and stored in dilute nitric or sulfuric acid. In addition, many samples contain significant amounts of dissolved nitrate and sulfate salts. Thus, during the desolvation stage of the atomization cycle there is a significant probability of formation of nitrate or sulfate salts.

Previous work in this laboratory¹ has demonstrated that nitrate and sulfate salts can cause significant analyte signal depressions above a graphite filament atomizer. Upon heating, the nitrate salts generally decompose in the following manner:^{2,3}

Similarly, the thermal decomposition of sulfate salts generally proceeds as follows:^{2,4}

The species NO_2 , SO_3 , O_2 , and to some extent SO_2 are

capable of gas phase oxidation of the free analyte atoms, thereby reducing the analyte free atom concentration and thus decreasing the analyte absorbance signal. The existence of the oxidizing species NO_2 and SO_2 within a graphite furnace atomizer has been confirmed by Yasuda and Kakigama.⁵ Their studies were conducted using relatively massive amounts of material and thus may mask the ability of graphite to remove oxidants through the formation of CO or CO_2 . Since the analyte absorbance signal persists for only a short period of time, gas phase coincidence of the interferent and analyte rather than the percentage decomposition may be the major factor in determining which nitrate or sulfate salt would exhibit the greatest signal depression.

Steady state experiments in which a large amount of the pure metal was placed in one well of the filament atomizer and either Na_2SO_4 , K_2SO_4 , NaNO_3 , or KNO_3 was placed in an adjacent well were conducted using the filament type atomizer. The temperature of the atomizer was raised and held at a constant value between 1300 and 1600 K. These experiments demonstrated that gas phase coincidence of the analyte and the interferent oxidant is

possible. It was suggested that the magnitude of the signal reduction was related to the concentration of the interferent in the gas phase, e.g., NaNO_3 caused a greater signal depression than KNO_3 since its equilibrium constant for decomposition (1.60×10^{-18} at 800 K) is approximately 10^{10} larger than is the equilibrium constant for KNO_3 (8.84×10^{-27} at 800 K). For the sulfates, K_2SO_4 caused a greater signal depression than did Na_2SO_4 . This again was consistent with the larger decomposition vapor pressures present using K_2SO_4 .¹

Transient experiments using the filament atomizer, in which nanogram amounts of sample and interferent were placed on the atomizer and the atomizer rapidly heated to 2000 K, also showed that these salts cause significant signal depressions for Ag, Cu, and Ga.

Other workers have obtained possibly contradictory results using the graphite filament atomizer. West et al have studied the effects of nitrates and sulfates on the absorbance signal of several elements.⁶⁻⁸ Depending upon the element, the addition of nitric or sulfuric acid to the matrix generally produced depressions, but in some cases enhancements were obtained.

2.2 Kinetic Studies

In 1979, Holcombe, Eklund, and Smith⁹ presented the thesis that kinetics may play an important role in gas phase interferent reactions above a graphite filament atomizer. Because of the small concentration of sample and interferent in the gas phase, local chemical equilibrium resulting from molecular collisions may not be established. Kinetics can be used to predict the extent of interference reactions.

For the bimolecular reaction:

where M is the analyte species and AB is the interferent the rate expression for the disappearance of the analyte with time is given as

$$\frac{-\delta [M]}{\delta t} = k [M] [AB]$$

where k is the second order rate constant. Assuming an excess of interferent AB, the rate equation may be reduced to a pseudo-first order kinetic expression

$$\frac{-\delta [M]}{\delta t} = k' [M]$$

where $k' = k[AB]$. Integration of the above rate equation allows the prediction of the rate of disappearance of the analyte with time.

$$\ln \frac{[M]_t}{[M_0]} = -k't$$

where $[M]_t$ is the concentration of the analyte at time t and $[M_0]$ is the concentration of the metal at time t in the absence of interferent AB.

Steady state studies of Fe, Sn, Cu, and Ga, with and without the addition of O_2 to the sheath gas, demonstrated that O_2 was effective in reducing the analyte absorbance signal. The reactivity of analyte with O_2 was experimentally determined to be $Sn > Ga > Fe > Cu$ while the order of reactivity based on thermodynamic prediction is $Sn > Fe > Cu > Ga$.³

Salmon and Holcombe¹⁰ have expanded on these studies using the transient absorbance signal, both with and without O_2 , to ascertain a relative rate of reaction for various metals. A more detailed description of this mode of obtaining relative kinetic data can be found in reference 9.

The results of these experiments for the metals investigated in this study are shown in Table I. As can be seen, the relative rates of reactivity for O_2 decrease in the order of $Sn > Cr > Fe > Cu, Ni > Ag$.

TABLE I

Ni	87	.30
Ag	33	.05

2.3 Thermodynamic Studies

Thermodynamics was originally used to explain the appearance temperature of certain elements by Campbell and Ottaway.¹¹ They postulated that free analyte atoms were produced by the reduction of the metal oxide by graphite.

Assuming that this reduction is kinetically fast, the temperature where ΔG° of the above reaction becomes negative was correlated with the appearance temperature of the analyte in a graphite furnace atomizer. Fairly good agreement was obtained for the majority of the twenty-seven elements studied.

Aggett and Sprott¹² studied the appearance temperature of several elements using both the graphite filament atomizer and the Ta ribbon analyzer. It was suggested that the appearance temperature differences between the two atomizers for the same analyte were indicative of the role of graphite in the formation of the free metal. In only four elements (Cu, Fe, Ni, and Sn) out of fourteen studied was the graphite considered an effective reducing agent of the MO species. More recently, Sturgeon, Chakrabarti, and Langford¹³

studied the mechanism of atom formation in the graphite furnace atomizer. Assuming equilibrium within the furnace, the activation energy of the atomization process was determined for several elements. Based on different activation energies, three mechanisms of atomization were proposed. Atomization can occur either by thermal dissociation of the metal oxide, thermal dissociation of the metal chloride, or reduction of the metal oxide by graphite followed by sublimation of the metal.

Frech and Cedergren investigated high temperature equilibria in graphite furnace atomizers.¹⁴⁻¹⁶ Using a sophisticated computer model, they studied the equilibria in several multicomponent interference systems. For the analysis of Pb in concentrated NaCl solutions, the addition of HNO₃ to the matrix resulted in the formation of NaNO₃ salts. If these salts were not removed during the ash stage of atomization the partial pressure of the oxygen generated during atomization was calculated to exceed 10^{-5} atmospheres. The decrease in sensitivity for Pb at low ash temperatures was attributed to the formation of lead oxide in the gas phase. They

also assumed that, in general, equilibrium within the graphite furnace atomizer can be rapidly obtained at temperatures above 1000 K.

CHAPTER III. EQUIPMENT

3.1 Commercial Graphite Furnace Atomizer Apparatus

The Varian Techtron CRA 90 graphite furnace atomizer is composed of two units, the workhead assembly and the atomizer power supply. The graphite furnace is 9 mm long with an inside diameter of 3 mm and is an adapted Massmann-type atomizer. The furnace is supported in the workhead assembly by two spring-loaded graphite support electrodes. These support electrodes are clamped to separate water-cooled metal support blocks on the workhead assembly. Both the furnace and support electrodes are made from pyrolytically-coated graphite. A laminar flow sheath gas with a flow rate of approximately 6 liters/minute surrounds the atomizer. The sheath gas is normally Ar or N₂, but it is possible to mix up to approximately 10% H₂ with these gases for certain analyses. The atomizer is resistively heated by the power supply which employs a voltage feedback circuit to attempt reproducible temperature-controlled heating of the atomizer.

The atomizer power supply has both time and temperature settings for the dry, ash, and atomize

stages. The dry temperature may range from room temperature to 300°C, while the dry time is variable from five to ninety seconds. During the ash stage temperatures up to 1700°C may be held for zero to sixty seconds. When the atomize cycle begins, the atomizer temperature is ramped at a rate between 25 and 800 degrees per second to any preset final temperature less than 3000°C and held at the final temperature from zero to five seconds. The maximum power fluctuation is claimed at $\pm 4\%$.¹

At the start of the atomization cycle the atomizer supplies a trigger input to the spectrophotometer. This circuit, which is activated by the closing of a relay in the power supply, synchronizes the measurement cycle with the atomization of the analyte.

Samples in liquid form are automatically deposited in the graphite furnace atomizer by the ASD 53 automatic sample dispenser. Sample volumes of either 2 μ l, 5 μ l, or 10 μ l are selected by changing a cam within the automatic sampler. Up to nine repetitions of 25 different samples may be selected for analysis.

The AA 375 spectrophotometer is a dual-beam spectrophotometer employing pulsed modulation of the

hollow cathode lamp and lock-in amplifiers to improve the signal-to-noise ratio. This spectrometer is capable of background correction using a deuterium lamp and will measure either the peak height or the peak area of the absorbance signal. A microprocessor automatically converts the transmittance readings, correcting for background absorbance if that option has been selected, into a three-decimal-place digital absorbance measurement which is displayed on the front of the instrument.

The same absorbance signal is fed through a manufacturer-supplied interface to a Hewlett-Packard HP 97 calculator where a permanent record of the absorbance signal is produced. Programs are available on the HP 97 which will correct for any absorbance of the blank, build an analytical working curve from the standards, and calculate the concentration of each unknown sample. For these studies, the instrument was used in the absorbance mode only and the calculator programmed to provide statistical information after a preselected number of repetitive samples were analyzed. The statistical program provides both an average absorbance and the relative standard deviation.

The transient absorbance signals are also supplied to a strip chart recorder as an analog input. For these studies a Linear Instruments Model 285/MM strip chart recorder was used to record the absorbance profile of the analyte.

3.2 Graphite Filament Atomizer and Optical System

A block diagram of the apparatus is shown in figure 1. A hollow cathode lamp (HCL) is used to provide the spectrum of the element under study. The lens (L) collimates the light from the hollow cathode lamp to provide nearly uniform light intensity in the region being viewed. The atomizer is a modified West-type filament atomizer that has been partially enclosed to minimize the entrainment of air. The filament is pyrolytically coated using the method of Szydolski et al.⁵ A laminar flow of Ar, typically at a flow rate of 2.5 liters/minute, further sheaths the filament from the outside environment. The atomizer power supply is capable of very rapidly raising the temperature of the atomizer at a rate of approximately 5000°/second. The final temperature of the atomizer is controlled by means of a photodiode feedback circuit which allows the atomizer to be reproducibly stepped and held at the selected final temperature. A trigger circuit provides a trigger pulse input to the Biomation Model 805 Waveform Recorder (Gould, Inc.; Biomation Division) when the atomizer temperature reaches a preselected value. A more complete description of the atomizer circuit is presented

Figure 1. Block Diagram of Filament Atomizer Apparatus

in reference 2. The height of the filament is adjusted to insure that the viewing zone is immediately above the atomizer surface.

The optical system for gathering simultaneous time and spatial absorbance information above a graphite filament atomizer has been described in the literature.^{3,4} Basically it employs off-axis imaging to produce the astigmatic tangential and sagittal images. Figure 2 is a representation of the basic optical system. The sagittal image is placed on the entrance slit of the monochromator, thereby allowing increased spectral intensity to reach the photomultiplier tube. The tangential image is repeatedly scanned by means of a precision-made rotating spatial isolation wheel (SIW) which has 60 radial slits (0.4 mm wide, 4.5 cm long) uniformly spaced around the 23 cm diameter wheel. The resolution of this apparatus has been experimentally determined to be limited by the slit width of the SIW, viz., 0.4 mm. It is this repeated scanning of the area above the graphite filament which provides the simultaneous time and spatial absorbance data.

The two MgF_2 -overcoated front surfaced spherical concave mirrors are arranged in an

Figure 2. Optical System for Producing Astigmatic Images

over-and-under configuration which provides the off-axis imaging. The spatial isolation wheel is located at the tangential image and is rotated at either 25, 50, or 100 rpm by means of precision-gear pulleys (PIC Design Corp.) and a no-slip positive drivebelt driven by a 100 rpm reluctance type synchronous motor (Hurst Mfg. Corp.). The selection of rotational speeds is dependent on the length of time the transient analyte signal persists.

The monochromator is a Jarrell Ash 0.5 m Ebert mount with an 0.5 mm entrance slit and a 0.6 mm exit slit. The output current of the 1 P28 photomultiplier tube (PMT) is passed through a parallel combination of a $.33\text{M}\Omega$ resistor and $.1\mu\text{F}$ capacitor to provide an output voltage with some high frequency noise rejection. The voltage drop across this resistor-capacitor pair is then fed to the Biomation recorder. The Biomation samples the PMT output at a predetermined rate, digitizes the analog input, and stores the signal in the 2048 eight-bit memory. This instrument has the capability of recording the data before and after the input trigger, delaying a predetermined amount of time and then recording, or recording the data immediately upon receipt of the trigger pulse. The

Biomation is interfaced to a microcomputer (Vector Graphics Model Vector 1) equipped with dual floppy disk drive which accomplishes data reduction, storage, and averaging. Generally five repetitions of each different sample or condition are recorded and averaged to produce a representative absorbance profile.

3.3 Optical System for Spatial Viewing Within the Graphite Furnace

The optical system used with the graphite filament was modified to allow gathering of simultaneous time and spatial absorbance data within the Varian CRA-90 atomizer (see figures 3 and 4). The filament atomizer assembly was removed from the system and an optical rail was installed upon which was mounted the hollow cathode lamp and its lens L_1 , the commercial furnace atomizer, and a magnification lens L_2 . Lens L_1 has a focal length of 12.5 cm, while lens L_2 is composed of two lens mounted back-to-back resulting in a focal length of 7 cm. Since the inside diameter of the furnace was only 3 mm, while the SIW apparatus and associated computer software was capable of viewing 9 one-mm zones, the furnace was magnified by a factor of three times by lens L_2 . Due to chromatic aberrations inherent in lenses, the furnace and L_2 must be repositioned along the optical rail for each element under study, i.e., for each change in wavelength. Since the basic graphite filament optical system provides unit magnification and optical resolution on the vertical plane above the filament atomizer, the furnace optical system is focused on this plane. The

Figure 3. Block Diagram of Spatially Resolved Furnace Apparatus

Figure 4. Optical System for Spatial Viewing Within the Furnace Atomizer

spatial resolution has been calculated at less than $220\mu\text{m}$ (see appendix A).

The furnace is aligned by rotating the SIW and viewing the PMT output on an oscilloscope. An approximate magnification was obtained from the visual image of the furnace on the SIW with the image of the furnace centered on the SIW field stops. The atomizer was brought into sharp focus by means of a horizontal grid which was clamped into the workhead assembly in place of the furnace. The furnace was then reinserted into the workhead assembly and the image centered on the monochromater entrance slit. If the magnification is correct, all nine zones of the SIW trace on the oscilloscope are illuminated. Overmagnification can be detected by moving the atomizer assembly horizontally a short distance. Since the optical system is now viewing a vertical chord of the furnace which is smaller than the furnace diameter, the display on the oscilloscope should indicate that not all nine zones of the SIW output are illuminated. If the alignment is incorrect, the furnace and/or the magnification lens is repositioned and the alignment procedure repeated.

At temperatures above 2100°C flare from the

magnification lens became a problem, especially for those elements whose resonance line was closer to the visible spectrum. The flare was minimized by placing an adjustable iris diaphragm between the lens and the first mirror. The aperture was reduced until it interfered with the magnitude of the PMT output. For all wavelengths used in this study, this was sufficient to reduce the magnitude of rod emission below detectability.

Because the optical system was extended by approximately one meter and the image magnified approximately three times, the hollow cathode lamp light intensity striking the photomultiplier tube was reduced. To restore the signal to an acceptable level required increasing the photomultiplier tube voltage and/or focusing the hollow cathode lamp output down into the furnace. Both these procedures introduced noise into the system.

A Hamilton 10 μ l syringe was used to place a 2 μ l aliquot of the test solution into the furnace through the sample introduction port in the atomizer. The furnace was heated by the commercial power supply to dry, ash, and atomize the sample. The trigger circuit in the atomizer power supply was modified to provide a positive trigger pulse to

the Biomation at the start of the atomization cycle. A battery was used to charge a capacitor to 1.5 volts. At the start of the atomization cycle, a relay in the commercial power supply closes allowing the capacitor to discharge through a resistor, thereby providing the trigger pulse to the Biomation.

The digital data from the Biomation is fed to the microcomputer (Vector Graphics Model Vector 1) where the different spatial zones are identified and the absorbance values calculated from the transmittance data. Another data reduction program averages together all the repetitions of each sample or condition to produce a representative profile. This program obtains the best alignment of the absorbance profiles for the first three spatial zones by shifting the data in time rather than just averaging together all the time-resolved absorbance data. This program calculates the percent deviation of each data set from the averaged profile and has the ability to eliminate one "bad" data set (>45% deviation in the first three zones) which exceeds the deviation criteria and calculates such fundamental parameters as appearance time, T_1 , T_2 , peak location, peak half width, in addition

to peak height and peak area.

CHAPTER IV: RESULTS AND DISCUSSION

4.1 Thermodynamics

Gas phase interferent reactions in flameless atomic absorption spectroscopy require that an interferent species must exist or be produced, that the interferent and analyte be temporally coincident, that thermodynamics favor the formation of the molecular species involving the analyte, and that the kinetics of the analyte-interferent reaction be sufficiently fast to deplete the gas phase analyte concentration.

Yasuda and Kakigama¹ have confirmed the existence of oxidizing species produced by the decomposition of nitrate and sulfate salts within the furnace atomizer. Eklund and Holcombe,² in transient studies with the filament atomizer, have demonstrated that temporal coincidence of analyte and interferent is possible for selected elements. The kinetic data of Holcome, Eklund, and Smith³ for the analyte oxygen reaction above a graphite filament atomizer suggest that Sn and Cr are kinetically fast and that a sufficient time may exist for equilibrium to be established. As shown in Table I, the other elements in this study

(Cu, Fe, Ni, Ag) are three to four orders of magnitude slower in their reaction with oxygen, and thus equilibrium may or may not be obtained.

To examine the role of thermodynamics in predicting or explaining the extent of interferent reactions, the following equilibrium expressions were considered:

The total partial pressure of the metal (P_{m}^{O}) is the sum of the partial pressures:

$$P_{\text{M}}^{\text{O}} = P_{\text{M}} + P_{\text{MO}} + P_{\text{MO}_2}$$

The total partial pressure of oxygen (P_{O}^{O}) is

also the sum of the component partial pressures:

$$P_O^O = P_O + 2P_{O_2} + P_{CO} + 2P_{CO_2} + P_{MO} + 2P_{MO_2}$$

From these equations an expression in terms of the partial pressure of oxygen (P_O^O), the partial pressure of the metal (P_M^O), and the equilibrium constants may be derived.

$$P_O^4 (2K_3^2 K_6 + 2K_1 K_6) + P_O^3 (K_6 + K_2 K_6 + 2K_3^2 K_5 + 2K_1 K_5) + P_O^2 (-P_O^O K_6 + K_5 + K_2 K_5 + 2K_3^2 + 2K_1 + 2P_M^O K_6) + P_O (-P_O^O K_5 + 1 + K_2 + P_M^O K_5) - P_O^O = 0 \quad (1)$$

The equilibrium constants at different temperatures were obtained from high temperature thermodynamic data⁴ and the relationship:

$$K_{eq} = e^{-\Delta G/RT} \quad (2)$$

If no thermodynamic data were available, the equilibrium constants were calculated from bond strengths and entropies of translation and rotation at various temperatures. The equation for entropy of translation⁵ is:

$$S_{TRANS} = R \left[\frac{5}{2} + \ln \frac{(2\pi mkT)^{3/2}}{h^3} v \right]$$

where:

R = ideal gas constant, 1.987 cal/mole -K

m = atomic mass in kg

k = Boltzman constant, $1.38 \times 10^{-23} \text{ J/K}$

T = temperature, Kelvin

h = Planck's constant, $6.62 \times 10^{-34} \text{ J sec}$

v = molar volume at temperature T , m^3

For a diatomic molecule the entropy of rotation is:⁶

$$S_{\text{ROT}} = R(1 + \ln \frac{8\pi I k T}{h^2})$$

where I is the moment of inertia as calculated by:⁷

$$I = \frac{m_1 m_2}{m_1 + m_2} r^2$$

The internuclear distance is r , and m_1 and m_2 are the respective masses of the atoms. The entropy of vibration is small and was neglected for these studies.

The total change in entropy (ΔS) of the metal oxide MO, free metal M, oxygen O system is:

$$\Delta S = S_{\text{MO}} - (S_{\text{M}} + S_{\text{O}})$$

where S represents the summation of the translational and rotational entropies of the respective species. Due to the lack of heat capacity data, the change in enthalpy of the metal oxide bond with temperature was assumed small.

From these data, the free energy of reaction, ΔG , for the reaction $M_{(g)} + O_{(g)} \rightarrow MO_{(g)}$ was calculated using the relationship:

$$\Delta G = \Delta H - T\Delta S$$

Equation 2 was then used to extract the equilibrium values. The results of these calculations were compared with published thermodynamic data at elevated temperatures for several metals and agreement to within 10% was found.

A computer program was developed to calculate the equilibrium distribution of the various species using equation 1. Without considering the role of graphite, i.e. omitting the first two equilibrium expressions, figures 5 and 6 illustrate the effects of an initial concentration of 10^{-3} atm of O_2 on the various elements. This oxygen concentration is comparable to the oxygen generated from the dissociation of 2 μ l of 100 ppm KNO_3 solution. In general these calculations would predict significant signal depressions from the metal-oxygen reactions below 2500 K. However, these calculations presume coincidence of interferent and analyte, do not consider the reaction kinetics leading to the formation of the metal oxide, and neglect the chemical role of graphite. When graphite is included in these calculations and its activity is assumed equal to one, greater than 95% of the metal is present as the free metal at

temperatures above the appearance temperatures of these metals. Thus in comparison to the filament atomizer where the analyte atoms are vaporized into free space, the furnace atomizer, which contains the analyte atoms within the high temperature graphite walls for a relatively longer period of time, should be more effective in minimizing interference due to metal oxygen reactions.

Due to the lack of a recording optical pyrometer with which to calibrate the filament and furnace atomizers, literature values of appearance temperatures of the elements were used throughout this study. L'vov⁸ has compiled various literature values of the appearance temperature and averaged them together to obtain a representative value. The arrows on figures 5 and 6 indicate the appearance temperatures of Cr (1740K), Ni (1675K), Fe (1580K), Cu (1460K), Sn (1620K), and Ag (1120K). These graphs may now be used to predict the relative effect of oxygen on the various metals in the study. Thus the depressive effect of oxygen on the analyte absorbance signal is greatest for Sn, followed in order by Fe, Cu, Cr, Ni, and Ag.

4.2 Experimental Procedure

The experimental parameters of the elements studied are given in Table II. Test solutions were prepared each day by dilution from concentrated stock solutions. Deionized, doubly-distilled water was employed for all dilutions. All glassware was cleaned with and stored in dilute HNO_3 . Prior to use, the glassware was thoroughly rinsed with the deionized, distilled water.

The wavelengths chosen for analysis were the most sensitive wavelengths recommended⁹ with certain exceptions. The intensity of the hollow cathode lamp at the most sensitive tin line, 234.8 nm, was so low that the 286.3 nm line was used. Photomultiplier tube noise was a major factor in the choice of wavelengths for the spatially resolved furnace studies. Thus the choice of the second most sensitive wavelengths for Ag, Ni, and Fe, as shown in Table II, permitted a lower baseline noise level.

In general, five repetitions of each sample or condition were conducted and the data averaged to produce a representative absorbance profile. The analyte solution without added interferent was normally analyzed both before and after the solutions containing interferent to verify that the atomizer

surface and other experimental variables had not changed. The interferent solutions consisted of the analyte to which was added either a ten-fold or a hundred-fold excess (weight-to-weight) of interfering anion to analyte. The interferent was either Na_2SO_4 , K_2SO_4 , NaNO_3 , or KNO_3 . Ashing temperatures were minimized in the furnace atomizer and the ash stage bypassed in the filament atomizer to insure the presence of interferent at the start of the atomization cycle.

The elements were selected for analysis based on their relative reaction rates with oxygen, the strength of the metal oxide bond, and their atomization temperatures. As shown in Table I, tin and chromium are both kinetically fast reactors with oxygen, yet the Sn absorbance signal appears some 120°C lower than Cr. Copper, iron, and nickel react moderately fast with oxygen. Nickel's appearance temperature is about that of Cr, while the appearance temperatures for Fe and Sn are approximately the same. Silver has the lowest appearance temperature of the elements studied and is also kinetically the slowest for the metal-oxygen reaction.

The experimental results for each element

are comprised of the peak absorbance measurements from the commercial apparatus, the time and spatially resolved studies above the graphite filament atomizer, and the time and spatially resolved studies within the furnace atomizer. These results are presented by element in the order of decreasing appearance temperature.

4.3 Chromium

As shown in Table I, chromium exhibited the second fastest reaction rate for the metal oxygen reaction. Its metal oxide bond strength of 102 kcal/mole is indicative of the thermodynamic driving force for this reaction. When the analyte absorbance signal is superimposed on the thermodynamic calculations (figure 7) it can be seen that different partial pressures of oxygen greatly affect the free Cr atom concentration. Utilizing figure 7, a partial pressure of oxygen greater than 10^{-4} atm. should produce significant signal depressions. These calculations presume coincidence of analyte and interferent oxygen, assume that kinetics are sufficiently fast to produce equilibrium, and discount the role of graphite in the equilibrium calculations.

FILAMENT ATOMIZER: Figures 8 through 11 display the results of the filament studies as a graph of the Cr peak absorbance signal vs the nine one mm viewing zones above the graphite filament atomizer. For a signal depression to be considered significant, the criteria was established that the analyte absorbance signal must decrease by more than one standard deviation from the absorbance

Figure 11. Filament Atomizer Results

signal of the interferent-free solution. Thus the solid lines on the graphs represent the \pm one standard deviation absorbance signal for the interferent-free analyte solutions. In figures 8 and 9, the chromium absorbance signal decreases very rapidly from its maximum value closest to the filament (zone 1) until it disappears into the baseline noise level at the fifth zone. No depressions were observed when either the sulfate or nitrate interferents were added to the analyte. The solutions containing Cr plus a hundred-fold excess of KNO_3 and the K_2SO_4 solutions exhibited slight enhancements in these viewing zones. The filament is completely enclosed by copper electrodes and quartz viewing windows to a height of approximately 2.5 cm above the filament. This enclosure is constantly flushed by the argon sheath gas. To minimize the entrainment of air from the top of the atomizer, the enclosure height can be increased a further 7.5 cm by placing a four-sided glass chimney on top of the atomizer. Figures 10 and 11 suggest that this chimney is effective in minimizing the entrainment of air into the atomizer. The Cr absorbance signal persists to at least the seventh viewing zone above the filament. Slight

depressions were observed for the interferent sulfate solutions.

FURNACE ATOMIZER: As shown in Table II, chromium required the highest final atomization temperature of the elements studied. As shown in figures 12 and 13, no signal depressions were observed for the added nitrates and sulfates. However, the presence of 1% of O_2 in the Ar sheath gas reduced the Cr absorbance signal magnitude by about 75%. This suggests that the absence of signal depressions results from the lack of gas phase temporal overlap between analyte and interferent.

SPATIALLY RESOLVED FURNACE ATOMIZER: Figures 14 and 15 illustrate that the Cr atoms are not uniformly distributed across the vertical diameter of the furnace. As discussed in the previous chapter, the optical system for the spatially resolved furnace studies gave a spatial resolution of approximately 0.3 mm in place of about 1 mm viewed in the filament atomizer. Even this magnified view, coupled with the increased residency time of the Cr atoms within the furnace and the potential effectiveness of metal oxide collisions with the hot graphite furnace walls are

insufficient to achieve uniform distribution of chromium atoms in the furnace atomizer. The three dimensional absorbance-zone-time graphs provide a picture of the entire absorbance profile. As shown in figure 16, the absorbance signal persists for about 800 msec. The absorbance is much higher in zone one, closest to the base of the furnace than in zone nine which is closest to the top of the furnace. The exact cause of the reduced free atom density near the center of the furnace is not known at this time. Similarly, the failure of the absorbance signal in zone 9 to reach the magnitude shown in zone 1 is inconsistent with a system at equilibrium if one assumes rapid diffusive mixing and a thermal gradient which is radially symmetrical. The signal enhancements due to the addition of a hundred-fold excess of Na_2SO_4 to the Cr solution were not observed on subsequent repetitions of this experiment on different days.

Figure 16. Absorbance Profile for Cr

4.4 Nickel

Nickel is comparable to Cr in its appearance and final atomization temperatures, yet the metal oxygen reaction for Ni is approximately 10^3 times slower for Ni than for Cr. As shown in Table I, the nickel-oxygen bond strength of 87 kcal/mole is about 20% lower than that of Cr. When the appearance temperature of Ni is superimposed on the results of the thermodynamic studies, as indicated by the arrow in figure 17, a partial pressure of oxygen in excess of 10^{-3} atm is required to significantly reduce the Ni free metal concentration. However, if graphite were considered in the equilibrium calculations, almost all the Ni would appear as the free metal even at an oxygen partial pressure as high as 10^{-2} atm.

FILAMENT ATOMIZER: Figure 18 demonstrates that the nitrate interferences produced no significant signal depressions using the graphite filament atomizer. Figure 19 shows similar results for added sulfates with the exception of a hundred-fold excess of K_2SO_4 . The three dimensional profile for the filament atomizer shown in figure 20 illustrates that in contrast to Cr, the analyte absorbance signal decayed less rapidly and

persisted for all nine viewing zones. This is consistent with the weaker Ni-O bond and the reduced reaction kinetics.

FURNACE ATOMIZER: As shown in figures 21 and 22, there were no absorbance signal depressions observed with the commercial apparatus. As with Cr, the absence of depressions may be attributed to the lack of gas phase coincidence of analyte and interferent. Additionally, as mentioned above, both kinetics and equilibrium considerations more strongly favor the existence of the free atomic species.

SPATIALLY RESOLVED FURNACE ATOMIZER: As illustrated in figures 23, 24, and 25, the free nickel atoms are fairly uniformly distributed throughout the vertical diameter of the furnace atomizer. That the maximum absorbance signal for each of the nine viewing zones occurs at approximately the same time indicates that diffusion from the bottom to the top of the atomizer is fairly rapid.

4.5 Iron

Many of the properties of iron are very similar to copper, e.g., its metal oxide bond strength (99 kcal/mole vs. 96 kcal/mole for Cu^{10}), and the kinetic rates for the formation of the metal oxide ($.45 \times 10^{-14}$ ml/molecule-sec vs. $.33 \times 10^{-14}$ ml/molecule-sec for Cu). Similarly, the equilibrium distribution diagrams for the two metals, ignoring the presence of graphite, as shown in figure 26 for Fe and figure 27 for Cu are very much alike. The tabulated average appearance temperature compiled by L'vov⁸ contain some temperatures which are inconsistent with the other values for the same element. The appearance temperature for Cu of 1730K, as observed by Campbell and Ottaway, is at least 300 degrees higher than the other Cu appearance temperatures. By removing this value, the recalculated Cu appearance temperature becomes 1367K. If the two graphs are shifted to superimpose the two appearance temperatures, which are indicated by arrows on the graphs, the thermodynamic profiles become almost identical. Thus, the similar response of the two metals to the added inter-ferents may be explained by the thermodynamic

Figure 26. Results of Thermodynamic
Calculations for Fe

Figure 27. Results of Thermodynamic Calculations for Cu

studies.

FILAMENT ATOMIZER: The peak absorbance signal vs. height above the filament atomizer are shown in figures 28 and 29. Slight depressions at elevated zones were observed for KNO_3 solutions. All the sulfate salts, with the exception of a ten-fold excess of Na_2SO_4 produced depressions. The depressions produced by the potassium sulfates were greater than those produced by the sodium sulfates. Figures 30 and 31 illustrate the absorbance-height-time profiles for the pure metal and Fe plus a hundred-fold excess of K_2SO_4 .

FURNACE ATOMIZER: As shown in figures 32 and 33, the interferences produced depressions in the furnace atomizer. The depressions appear to be fairly independent of interferent concentration and the type of interferent. This random ordering of depressions may be due to changes in the activity of the graphite. As noted earlier, if graphite was considered to have unit activity almost all the analyte (greater than 95%) would exist as the free metal at temperatures greater than the appearance temperature. Thus, small changes in the activity of graphite would account for the day-to-day variation in the magnitude and order

of the depressive effects of the interferent salts.

SPATIALLY RESOLVED FURNACE ATOMIZER:

Depressions were again apparent in the spatially resolved furnace studies. As is shown in figures 34 and 35, these depressions were again in somewhat of a random order. The three-dimensional absorbance-zone-time graphs (figure 36) illustrate that the Fe atoms, like Ni, are fairly uniformly distributed across the vertical diameter of the furnace.

4.6 Copper

As noted previously, copper and iron are very similar in their kinetic and thermodynamic properties for the formation of the metal oxide.

FILAMENT ATOMIZER: Figures 37 and 38 show that the addition of nitrate and sulfate salts to the Cu solution cause significant analyte signal depressions. As predicted from the relative magnitude of their decomposition constants, K_2SO_4 depressed the analyte signal to a greater extent than did Na_2SO_4 . For the nitrates, KNO_3 showed a greater interferent effect than $NaNO_3$. The absorbance-height-time profiles for the filament atomizer illustrate that the depressive effects of the concomitant salts are greatest at the elevated zones (figures 39 and 40). This suggests that reaction kinetics have yet to produce equilibrium.

FURNACE ATOMIZER: In the furnace atomizer studies, figures 41 and 42, depressions were again observed, although the day-to-day reproducibility was poor. As with iron, the depressions appear to be independent of the type of salt or concentration.

SPATIALLY RESOLVED FURNACE ATOMIZER:

Depressions were also noted in the spatially resolved furnace data. Figures 43 and 44 indicate that the free copper atoms, while slightly higher near the furnace base, are fairly evenly distributed throughout the furnace volume. The three-dimensional graphs, figures 45 and 46, illustrate the depressive effects of the interferent.

4.7 Tin

Tin was the most interesting element examined. The equilibrium distributions shown in figure 47 indicate that if the role of graphite is ignored, the Sn appearance temperature of 1620K^8 is such that almost all the free metal is removed by the presence of even a small amount of oxygen. However, the inclusion of graphite in the thermodynamic calculations again results in nearly all of the metal being present as the free metal. As shown in Table I, tin has the highest kinetic rate constant for the metal oxygen reaction of the elements studied. Fontijn et al,¹³ in studies at room temperature, suggest that the metal oxygen reaction approaches a collision rate limited condition. Its metal oxide bond strength of 125^{10} kcal/mole is at least 20% higher than the other elements in this study.

FILAMENT ATOMIZER: The graphite filament atomizer could not be employed for the analysis of Sn. With the present system configuration, the Sn absorbance signal was very erratic in the spatial zone closest to the filament surface and did not persist past the second viewing zone.

Figure 47. Results of Thermodynamic Calculations for Sn

Perhaps with better exclusion of oxygen, the filament atomizer could be used for the analysis of Sn.

FURNACE ATOMIZER: The entrained oxygen, which was believed responsible for the failure of the filament atomizer to generate a reproducible absorbance signal, was minimized by one of two methods. Approximately 10% H₂ (flow rate of .6 l/min) was introduced into the Ar sheath gas during the ash and atomization cycles. The hydrogen provides a strongly reducing environment for the analyte as well as removing oxygen. Indeed, a hydrogen-diffused flame is observed during the atomization cycle. The commercial instrument was modified by enclosing the entire atomizer assembly and the automatic sample dispenser carrousel in an air-tight box which was continuously flooded with Ar (figure 48) introduced through the gas box of the atomizer. As the box filled with the more dense Ar, the entrained air was purged from the atomizer. The pressure within the enclosure box was maintained at slightly greater than one atmosphere by allowing Ar to escape from the box.

Both the systems proved effective in

Figure 48. Furnace Atomizer Enclosure Box

stabilizing and enhancing the tin absorbance signal. As is shown in figure 49, a significant shift in the analyte absorbance appearance time, which can be related to an atomizer temperature change of approximately 380°C, was noted for both the H₂ rich environment and the atomizer enclosure box in comparison to just using Ar sheath gas in the unmodified atomizer enclosure. This change in the appearance time suggests a change in the release mechanism of Sn from the atomizer surface due to the presence or absence of oxygen. The exact nature of this change is not presently known. These results confirm the importance in minimizing the entrainment of air as first suggested by Guiochon et al¹¹ and Eklund and Holcombe.¹²

Dramatic signal depressions were observed for the tin and hundred-fold excess of sulfates while using H₂ added to the sheath gas. As can be seen in figure 50, the tin absorbance signal is reduced to a value comparable to the background noise level. The effects of the addition of equal amounts of sodium or potassium sulfate to the tin solution are shown in figure 51. While a measurable signal was still detected, it was

Figure 50. Furnace Atomizer Results

TIN

PEAK HEIGHT

Figure 51. Furnace Atomizer Results

significantly depressed. Two- and three-fold excesses of these salts once again completely suppressed the analyte absorbance signal as can be seen in figure 51. Ashing the samples up to 750°C for 20 sec was not sufficient to eliminate the signal depressions. This suggests that the interferent was not decomposed and volatilized during the ashing stage. Ashing at temperatures above 750°C resulted in loss of the analyte. The addition of 1% oxygen to the argon sheath gas while using the atomizer enclosure box also reduced the tin absorbance signal below the level of detectability.

SPATIALLY RESOLVED FURNACE ATOMIZER:

Spatial studies within the graphite furnace atomizer employing H_2 added to the sheath gas also showed depressions. As can be seen in figure 52, the free tin atoms were not evenly distributed within the viewing zones of the atomizer. This suggests that H_2 was not totally effective in removing all the entrained oxygen. The absorbance signals for the addition of two- and ten-fold excess Na_2SO_4 and two-fold excess K_2SO_4 were very small in the first zones and rapidly decayed to the baseline noise level within the first

4.8 Silver

Silver exhibited the lowest appearance temperature of the elements studied. As shown in table I, the metal oxide bond strength of 33 kcal/mole is also the weakest and is indicative of the thermodynamic driving force of the silver oxygen reaction. The results of the thermodynamic studies are shown in figure 55. These calculations, which omit the role of graphite, illustrate that no analyte signal depressions would be expected from partial pressures of oxygen as great as 10^{-2} atm. Previous kinetic studies in this laboratory (Table I) indicate that the silver oxygen reaction kinetics are very slow in comparison to the other elements studied.

FILAMENT ATOMIZER: As illustrated in figure 56, the sulfate interferents produced no significant signal depression using the filament atomizer. Figure 57 shows only a slight depression with a hundred-fold excess of KNO_3 . The three-dimensional profiles for the filament atomizer, as shown in figure 58, illustrate the rapid absorbance signal decay from the first viewing zone to zone nine.

FURNACE ATOMIZER: There were no absorbance signal depressions observed with the commercial apparatus. This is consistent with the kinetic and equilibrium considerations which do not greatly favor the formation of the metal oxide.

SPATIALLY RESOLVED FURNACE ATOMIZER: As shown in figures 59 and 60, depressions were observed for the nitrate interferents, while no depressions were observed for the addition of sulfates to the analyte solution. This was consistent with the results of the filament atomizer study. The absorbance-time-height graph, figure 61, illustrates that the free Ag atoms are uniformly distributed across the vertical diameter of the furnace atomizer.

4.9 Conclusions

The extension of the unique optical system for obtaining simultaneous time and spatial resolution to the commercial furnace atomizer has enabled a preliminary study of gas phase reactions within the furnace atomizer. As the experimental results demonstrate, gas phase coincidence of analyte and interferent appears imperative if absorbance signal depressions from concomitant salts are to occur. Thus, those elements with higher appearance temperatures, e.g. nickel and chromium, probably did not encounter the interferent oxidant produced from the nitrate and sulfate salts used in this study.

Once the coincidence of analyte and interferent has been established, kinetics may limit the extent of the interference reaction. In the filament atomizer the interaction time between the metal and oxidant within the viewing zone is approximately 20 msec. Similarly, the thermodynamic driving force for the formation of the metal oxide is greater for the filament atomizer due to the likelihood of reduced gas phase temperature at elevated distances above the heated surface in comparison to the enclosed analytical volume of the

furnace atomizer. Residence time within the furnace, as measured by the absorbance signal time profile is between 400 and 800 msec. These differences in temperature and time may be critical for elements such as Cu and Fe which exhibit interferences using the filament but not the furnace. However, with tin which forms a stable oxide and exhibits rapid kinetics, severe depressions are observed for both atomizer types. To effectively probe the reaction kinetics within the furnace atomizer, better time resolution may be required. With the present experimental arrangement, this simply requires increasing the SIW rotation velocity. However, to accommodate the increased sampling rate, the memory capacity of the sampling device needs to be expanded. Perhaps analog to digital conversion with direct data stored into the memory of the microcomputer could be utilized. In either instance it should be recognized that the photomultiplier tube/hollow cathode lamp noise may be a limiting factor in the success of this approach. The incorporation of new lamp designs with higher intensity and better stability would make this approach more tractable. To completely understand these reactions, a probe of the molecular species

is required. Mass spectroscopy would allow more complete monitoring of both reactants and products of any reaction, as well as the determination of the appearance temperature of interferent species in gas phase.

The thermodynamic model, which was developed to predict or explain the extent of analyte absorbance signal depressions due to the formation of the metal oxide, is handicapped by the requirement to ignore or reduce the influence of the graphite in the equilibrium calculations. With the assumption of total chemical equilibrium including the graphite, calculations indicate that no signal depressions should occur for any of the elements studied. The fact that depressions were observed indicates that graphite is only partially effective in removing oxygen within the atomizer and/or reducing the metal oxide bond. Further studies, perhaps utilizing such surface probes as Auger spectroscopy, ESCA, or scanning electron microscopy, aimed at elucidating the role of graphite in the atomization process would enhance this thermodynamic model.

The appearance time shifts, which were observed for the addition of H_2 to the Ar sheath

gas in the Sn study, suggest that different analyte release mechanisms from the graphite surface were occurring. These shifts in appearance time have not been observed for Sn prior to this study, however timeshifts for the more volatile elements, e.g. Pb and Zn, are well documented.¹⁴ The fundamental cause of these time-shifts is presently under study in this laboratory. Another interesting study would be to chemically modify the graphite surface to delay volatilization of the analyte until the furnace reaches a higher temperature. This higher analyte appearance temperature might serve to minimize some interference effects. Modification of the graphite by forming refractory metal carbide surfaces have been considered by a few investigators, although the studies to date have been fairly pragmatic and focus only on the analytical utility of these surfaces with little emphasis on the chemical basis for observed absorbance signal changes. These metal carbide surfaces are fairly inert, which deprives the chemical system of the reducing ability of the graphite.

The importance of minimizing the entrainment of air into the atomizer was demonstrated

in both the Cr and Sn studies. Other commercial furnace atomizers are available which completely enclose the atomizer in a pressurizable housing. These atomizers allow for stopping the Ar sheath gas during the atomization cycle. This design would better enable a study of the effects of reactive gases, such as O_2 , and the role of graphite on the analyte absorbance signal. Due to the open design of the present atomizer, it is impossible to stop the gas flow during the atomization cycle. Thus additional variables, such as the effects of connective mass transport near the ends of the furnace, cannot be eliminated. Conversely, the totally enclosed atomizer would allow an initial assumption of diffusion-controlled mass transport to be made, as a first step in modeling this system.

In summary, this work has demonstrated that:

- 1) The simultaneous collection of time and spatial absorbance data within the 3 mm diameter commercial furnace atomizer is feasible. The information available from the time and spatial absorbance maps appears to augment the simple absorbance-time data that can be conventionally

obtained.

2) Several gas phase interferent reactions observed previously in the filament atomizer also exist within the furnace atomizer.

3) The elevated gas temperature and/or the presence of a second graphite collision surface within the furnace is effective in reducing the depressive effects of concomitant nitrate and sulfate salts which previously exhibited depressions with the filament.

4) Total chemical equilibrium inclusive of the graphite is unlikely and reaction kinetics and/or mass transport of oxidants and metal oxides to the graphite surface may reduce the effectiveness of the graphite surface.

5) Gas phase coincidence between the thermal decomposition products of the concomitant and the analyte appears to play a significant role in determining the extent of the interferences.

APPENDIX A: CALCULATION OF SPATIAL RESOLUTION WITHIN
THE FURNACE ATOMIZER

With the center of the furnace in sharp focus, a wire grid of known dimensions was inserted into the atomizer workhead assembly in place of the atomizer. The spatial isolation wheel (SIW) was rotated and the resulting output recorded by the Bio-mation and plotted on a strip chart recorder. Strip chart recordings were also obtained for the images of the wire grid at either end of the furnace atomizer. The distance between the wire grid was measured by an optical micrometer as .0381 cm. The distance between the two field stops immediately in front of the SIW was measured as .9335 cm.

The magnification was determined by the distance between adjacent grid peaks compared to the distance between the SIW peaks. Therefore, at the center of the furnace the strip chart recording showed:

SIW peak-to-peak distance = 52.4 cm

Grid peak-to-peak distance = 8.1 cm

Half width of grid peak = 2.5 cm

The magnified distance, d_m , between the center of two adjacent grid wires was:

$$d_m = \frac{(8.1 \text{ cm})(0.9335 \text{ cm})}{52.4 \text{ cm}} = 0.144 \text{ cm}$$

The magnification, m , of the optical system was obtained by dividing the magnified grid spacing by the measured grid spacing:

$$m = \frac{.144 \text{ cm}}{.03810 \text{ cm}} = 3.78$$

The magnified resolution, Δd , was determined by the half width of the grid peak relative to the SIW peak-to-peak distance. Thus, at the center of the furnace:

$$\Delta d = \frac{(2.5 \text{ cm})(0.9335 \text{ cm})}{52.4 \text{ cm}} = 0.0445 \text{ cm}$$

Division of the magnified resolution by the magnification yields the optical resolution, R_o , within the center of the furnace:

$$R_o = \frac{0.0445 \text{ cm}}{3.78} = .0118 \text{ cm}$$

The optical resolution at the end of the furnace closest to the hollow cathode lamp was calculated at $211\mu\text{m}$ with a magnification of 3.66, while the resolution at the end of the furnace closest to the SIW was $194\mu\text{m}$ with a magnification of 3.72.

The data collection program divides the

distance between the SIW field stops into ten zones. Subsequent division by the magnification yields the sampling resolution, R_s , at the center of the furnace atomizer:

$$R_s = \frac{.09335 \text{ cm}}{3.71} = .0252 \text{ cm}$$

Thus, the worst optical resolution of $211\mu\text{m}$ is less than the sampling resolution of $252\mu\text{m}$.
